A Search for Leptoquarks, Leptogluons and Excited Leptons in H1 at HERA

H1 Collaboration

Abstract:

A direct search for new particles in the H1 experiment at HERA is presented for masses ranging from 35 GeV up to ~ 250 GeV. The data sample of 24 nb^{-1} accumulated during the first year of operation was analysed for signatures of scalar and vector leptoquarks, leptogluons, excited electrons and excited neutrinos with flavours of the first generation. No evidence for the production of such particles was found in various possible decay channels. Rejection limits are derived.

1 Introduction

The Standard Model of strong and electroweak interactions based on the $SU(3) \otimes SU(2) \otimes U(1)$ gauge group has been successful in describing the phenomenology of high energy particle physics. Nevertheless many fundamental facts, such as the quark-lepton symmetry or the existence of three generations of fermions and their mass spectrum remain unexplained by the model. New states that are not contained in the Standard Model particle spectrum would strongly influence the construction of new theories explaining these facts. A search for new particles is therefore a priority task at any new accelerator.

The ep collider HERA is an ideal machine to look for leptoquarks and leptogluons that could be produced as s -channel resonances in the electron-parton system. Coloured leptoquark bosons appear naturally in many theories that extend the symmetry of the Standard Model in order to unify the known forces (e.g. grand unified theories [1], superstring inspired models [2]), or models postulating a new interaction (e.g. technicolour [3]), or in some composite models [4]. Leptogluons are predicted in those composite models where the weak gauge bosons and the leptons are bound states of coloured constituents [5]. The search for excited electrons is an obvious field of interest in electron scattering experiments. Excited states of known leptons are a natural ingredient of composite models [6]. If found, they would constitute a strong proof for the existence of a new layer of structure in leptons. HERA provides direct access to a new region of possible values for the masses and coupling constants of these particles.

Although leptoquarks, leptogluons and excited leptons arise in very different theoretical models they have a basic feature in common from a phenomenological point of view. All states discussed in this paper are formed as a resonance between the incoming electron and a constituent of the proton or a gauge boson radiated off the proton. In the narrow width approximation and to lowest order, the ep cross section for the production of a heavy state H decaying into a specific final state with a branching ratio \mathcal{B} is given by:

$$\sigma(ep \rightarrow H + X) = \frac{4\pi^2}{s} (2J+1) \frac{\Gamma}{M} \mathcal{B} f_{ip}(M^2/s)$$

where J , M are the angular momentum and the mass of H , and \sqrt{s} is the centre of mass energy. The term $f_{ip}(x)$ denotes for example the quark density functions or the number of photons $f_{\gamma p}(x)$ radiated off the proton - as appropriate. The widths Γ and the branching ratios \mathcal{B} contain the dependence on the couplings of the new particles.

In this paper, we present a search for direct single production of new particles based on an integrated luminosity of $\mathcal{L} = 24 \pm 2 \text{ nb}^{-1}$ collected during 1992 at $\sqrt{s} = 296 \text{ GeV}$. Early results from HERA have already been presented [7].

2 Experimental Set-up

A detailed description of the H1 detector can be found elsewhere [8]. Here we briefly describe the components relevant for the present analysis.

The interaction vertices along the z -axis are distributed symmetrically around the centre of the H1 coordinate system¹ and $\sim 90\%$ of ep events are contained within the magnetic backward calorimeter extends the coverage at larger angles ($135^\circ \leq \theta \leq 170^\circ$). In the LAr calorimeter, electron energies are measured with a resolution of $\sigma(E)/E \approx 5\%/\sqrt{E}$ and hadron energies with $\sigma(E)/E \approx 50\%/\sqrt{E}$ after software energy weight.

¹The positive x -coordinate (i.e. forward direction) from which the θ polar angle is defined to coincide with the direction of the incident proton.

interval $|z_{\text{pix}}| < 50 \text{ cm}$. The tracks of the emerging charged particles are measured array of central and forward drift and proportional chambers covering the angular range $7^\circ \leq \theta \leq 176^\circ$.

The tracking system is surrounded by a finely segmented liquid argon (LAr) sam calorimeter covering $4^\circ \leq \theta \leq 155^\circ$ with a thickness varying between 20 and 30 radius lengths for the lead/argon electromagnetic section and from 4.5 up to 8 interaction lengths in total including the stainless-steel/argon hadronic section. A lead/scintillator elec magnetic backward calorimeter extends the coverage at larger angles ($135^\circ \leq \theta \leq 170^\circ$). In the LAr calorimeter, electron energies are measured with a resolution of $\sigma(E)/E \approx 5\%/\sqrt{E}$ and hadron energies with $\sigma(E)/E \approx 50\%/\sqrt{E}$ after software energy weight.

The tracking chambers and calorimeters are surrounded by a superconducting solenoid providing a uniform field of 1.2 T parallel to the z -axis within the tracking volume. The return iron yoke surrounding this coil is fully instrumented to measure leakage hadronic showers and to recognize muons. Muon tracks are measured in layers of straw tube chambers between $5^\circ \leq \theta \leq 170^\circ$. The system is completed by a forward mu spectrometer in the region $3^\circ \leq \theta \leq 17^\circ$.

The luminosity is determined from the rate of the Bethe-Heitler $ep \rightarrow e\gamma\gamma$ process measured in a luminosity monitor as described in [9].

3 Leptoquarks

3.1 Phenomenology

Leptoquarks are colour triplet bosons carrying a fractional electric charge and both baryonic and leptonic quantum numbers. They may couple to electroweak bosons, gluons and electron-quark ($e\bar{q}$) pairs, whereas at accessible masses their coupling to $q\bar{q}$ pairs vanish to avoid fast proton decay. In ep collisions at HERA, the dominant production could be by direct resonant $e\bar{q}$ fusion in the s -channel. This is unlikely at other current colliders where the production would be dominated by production either via s -channel electroweak gauge boson exchange (in $e^+\bar{e}^-$ collision via gluon-gluon fusion or $q\bar{q}$ annihilation (in $p\bar{p}$ collisions).

At HERA, besides the dependence on the electric charge, the spin and the isospin, leptoquark production also depends on the strength of unknown Yukawa couplings λ to the $e\bar{q}$ pairs. In this paper, we consider the most general effective lagrangian [10] for baryon and lepton number conserving scalar and vector leptoquarks having dimensionless, $SU(3) \otimes SU(2) \otimes U(1)$ invariant couplings to fermions. Isospin families of allowed leptoquarks are given in table I where we adopt the nomenclature from [11].

Given the severe low energy experimental constraints on flavour-changing transitions [12], we assume that intergenerational mixing is forbidden and that first generation leptoquarks are only allowed to decay into fermions of the same generation. More there are limits and precision measurements on branching ratios of pseudoscalar and decays that constrain most leptoquarks with masses M of $\mathcal{O}(100) \text{ GeV}$ to have sizeable couplings only to either left handed or right handed leptons [12].

which distinguishes them from the $1/y^2$ spectrum yielded by standard vector boson exchange.

Direct searches for scalar leptoquarks have been carried out by e^+e^- collider experiments at PETRA [13, 14], TRISTAN [15] and LEP [16], as well as at $p\bar{p}$ collides at the UA1 and UA2 experiments at CERN [17] and by CDF at Fermilab's Tevatron. In most cases, the rejection limits were obtained for some scalars with specific quark numbers. Nevertheless, these limits should only weakly depend on these choices. At confidence level (CL), the LEP experiments exclude the domain $5 \lesssim M_S \lesssim 45$ GeV (UA2 and CDF (preliminary results) exclude $30 \lesssim M_S \lesssim 82$ (113) GeV for a 50% (1 \mathcal{B}) into $e + X$, almost independently of the coupling λ .

Finally, it should be noted that an indirect limit of $\lambda_L \lesssim M/1.7$ TeV has been arrived [12] from the universality of the Fermi constant measured in μ decays and β decay. Leptoquark exchange with left handed couplings could contribute to the latter. Limit would however be weakened if the Standard Model prediction for the these $d\bar{d}$ modified, for instance, by additional Higgs scalars.

3.2 Event Selection and Kinematics

A high transverse energy E_T in the final state is a basic feature for leptoquark events for large masses since E_T^* for $e+X$ decays and E_T^* for $\nu+X$ form a Jacobian peak at \approx . In contrast, the background from photoproduction is concentrated at low E_T .

Hence, for $e+X$ final states, a relatively clean sample of candidate events (from high Q^2 neutral current DIS) is obtained by searching for a high E_T electron in the final state. The events are required to have been registered by LAr triggers based on the measured total or transverse energy. All the relevant hardware triggers simultaneously operational for $\approx 85\%$ of the integrated luminosity. We require an electron candidate with $E_T^* > 10$ GeV is found in the fiducial volume of the calorimeter and at $\theta_e > 10^\circ$. The e.m. shower must have at least 90% of its energy deposited in the e.m. section. In addition the shower must be isolated in the ϕ direction that there should be less than 10% additional hadronic energy within a cone of azimuth angle ϕ and pseudorapidity η of opening $\sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.5$ centered on the candidate electron and viewed from the interaction vertex. The accepted events are required to be reconstructed vertex. In events where several 'electron' candidates were found, the with the highest E_T^* was assumed to originate from the decay (i.e. to be the scatterer). The electron energy E_e and the angle θ_e are calculated entirely from energy deposits in the LAr calorimeter viewed from the interaction vertex. The angular resolution obtained is of about $\sigma_\theta \simeq 0.7^\circ/\sqrt{E}$ (E in GeV). The method of calculating the mass well suited to the leptoquark mass reconstruction at large y , our region of interest.

Table 1: Isospin multiplets T of scalar ($^Q S_T$) and vector ($^Q V_T$) leptoquarks with electric charge Q , branching ratio \mathcal{B} , and fermion number $F=2$ or $F=0$, and the allowed production and decay channels for first generation leptoquarks at HERA (e^- beam). A coupling value $\lambda_{L(R)} \neq 0$ allows for processes with incident $e_L^- (R)$.

In the following, we consider the fixed branching ratios \mathcal{B} into the $e+X$ and $\nu+X$ final states given in table 1. We do not distinguish between the various charge states of a given isospin family and assume mass degeneracy within each family. Hence we are left with 10 types of leptoquarks that would all have, to lowest order, a final state consisting of a spectator jet from the proton remnant together with a lepton and a jet from the decay of the resonance balancing each other in transverse momentum P_T . This signature is indistinguishable from that of the neutral and charged current modes in deep inelastic scattering (DIS). Therefore these processes represent the most severe sources of background events and can only be subtracted statistically.

To lowest order and in the narrow width approximation, the total leptoquark production cross sections only depend on the square of the dimensionless coupling constant λ and the quark density of the quark flavour(s) involved in the process. The partial decay widths are given by $\Gamma_s = (\lambda^2/16\pi) M$ for scalar and $\Gamma_V = (\lambda^2/24\pi) M$ for vector leptoquarks. For the smallest couplings accessible here (see section 3.3) the decay widths are as small as ~ 3 MeV for $M \simeq 50$ GeV but reach $\gtrsim 2$ GeV at $M \simeq 200$ GeV. Hence, except for the highest masses, leptoquarks of mass M would appear as narrow resonances with an observed width dominated by detector resolution and centered at a value of Bjorken scaling variable x given by $M = \sqrt{(p_e + p_\theta)^2 \simeq \sqrt{x}s}$, where p_e, p_θ denote the four-momenta of the beam electron and the incoming quark. For the couplings and resolutions expected in this analysis, the contribution of the interference with DIS diagrams to the cross section in a $[M \pm 3\sigma_M]$ bin centered on the resonance is less than $\pm 1\%$ for $F=2$ and $\pm 5\%$ for $F=0$ leptoquarks up to the highest mass considered and is henceforward neglected.

Further separation from the DIS background will be possible in particular for scalar leptoquarks that decay isotropically and correspondingly yield a flat distribution in y

We require a matching between the Bjorken y_e variable measured with the electron and y_h measured via the hadronic flow, $|y_e - y_h| < 0.3$ where

$$y_e = 1 - \frac{E_e - P_{z,e}}{2E_e} \quad \text{and} \quad y_h = \frac{E_h - P_{z,h}}{2E_e}$$

Here the subscript h denotes the sum over all particles measured in the LAr calorimeter excluding the electron candidate. Besides removing events where a hard undetected photon was radiated from the initial state electron, the main purpose of this cut is to reject photoproduction events with a misidentified ‘electron’ candidate in the LAr calorimeter and for which the scattered electron usually escapes undetected at low scattering angle in the beam pipe. The remaining event sample was visually scanned and one further cosmic muon event was identified and rejected. Although we impose no explicit matching requirement of the electron shower with an inner central or forward track, all electron candidates of the final sample were accompanied by at least one reconstructed track within the isolation cone. After all selections have been applied, 43 events remain with reconstructed ‘leptoquark’ masses above 35 GeV.

A search for final states with $\nu + X$ is made by requiring a missing transverse momentum of $P_T^{\text{miss}} \equiv \sqrt{(\sum E_x)^2 + (\sum E_y)^2} > 20$ GeV measured by the calorimeters. Any event with an electron candidate (as defined above) with $E_T^e > 10$ GeV are rejected. Cosmic muon induced showers were recognized and rejected on the basis of back-to-back tracks in the muon system. Five events with clear cosmic induced patterns were finally rejected at a visual scanning. One event with a $P_T^{\text{miss}} = 37$ GeV remained, showing the expected signature of a high P_T current jet together with the energy flow from the proton remnant. The leptoquark mass for this event was calculated via the Bjorken x variable computed from the hadronic energy flow, $M = \sqrt{s_{Xh}}$ with

$$x_h = \frac{P_{T,h}^2}{(1 - y_h) y_h s}$$

The calculated mass of this $\nu + X$ candidate is 93 GeV.

3.3 Results

We first compare our $e + X$ data sample with a Monte Carlo simulation. For the DIS neutral current background, we used the DJANGO event generator [19] which provides an interface to HERACLES [20] for the standard electroweak interactions including first order QED radiative corrections, and LEPTO [21] for QCD corrections (leading log parton showers). The Lund string model is used for fragmentation and decay. The events were passed through the full HI simulation and reconstruction chain. The trigger efficiencies, monitored by using track triggers, were folded in.

Figure 1 (a) shows the measured P_T^{miss} for the 43 events compared to the DIS event simulation. The events are well balanced in the transverse plane and the DIS Monte Carlo reproduces well the tail of the P_T^{miss} distribution which is due to detector resolution and energy losses. The electron E_T extends up to 50 GeV and was found to be very well correlated with the total E_T flow. The electron carries on average about 45% of the total E_T , as one might anticipate for an $e + \text{jet}$ final state given the broadening of the jet caused by parton shower and fragmentation effects. The mass distribution is shown in

Figure 1: P_T^{miss} distribution (a) and mass spectrum (b) for $M = \sqrt{s_{\nu e}} > 35$ GeV before (open points) and after (closed points) the final kinematical cut on y_e . The histogram curves show the absolute prediction of a DIS Monte Carlo simulation based on DJANGO simulation before (dashed) and after the (solid) kinematical cut.

fig. 1 (b) before and after a final kinematical cut of $y_e > 0.25$. This cut was chosen a compromise to optimise the signal-to-background ratio for scalar leptoquark search while maintaining efficient detection of vector leptoquarks. It also safely rejects the y region where both y_e and x_e are badly measured. In fig. 1, both the absolute number of events and the shape of the mass spectra are well reproduced by a DIS Monte Carlo simulation before and after the y_e cut.

For $\nu + X$ final states, we apply no additional kinematical cuts compared to the DIS described in section 3.2. Using DJANGO as the basis for event simulation and reconstruction and folding in the LAr trigger efficiencies for the hadronic flow, one predicts the differential cross section in the electron initial state y region where both y_e and x_e are badly measured. In fig. 1, both the absolute number of charged current events of 0.66. We now derive rejection limits for the hypothesis that all observed events are standard DIS background. To compute efficiencies for the various leptoquark types we make use of the COMPASS event generator [11] which implements the differential cross section calculated in [10] and which includes radiative corrections in the electron initial state the collinear approximation. It should be noted that the parton showering (here generated through the Lund model) is only applied to the final state quark (i.e. a leptoquark decay) and to the ‘diquark’ remnant of the proton. This is despite the fact for low masses and couplings (e.g. $M_S \lesssim 100$ GeV, $\lambda \lesssim 0.1$), the lifetime of the leptoquark

is such ($\tau \gtrsim 3 \times 10^{-23} s$) that it must itself participate in the fragmentation before decaying. Such a crude approximation is justified if one considers that leptoquarks may have ‘hard’ fragmentation functions not unlike those of heavy quarks. The mass resolutions $\sigma_{S,V}$ roughly scale with mass at small coupling values (e.g. $\lambda \lesssim 0.3$) for which the intrinsic width of the resonance can be neglected. We find that $\sigma_S = 1.1 \text{ GeV} + 9.6 \times 10^{-3} M_S$ for scalars and $\sigma_V = 1.9 \text{ GeV} + 9.0 \times 10^{-3} M_V$ for vector leptoquarks in the charged decay mode while in the neutral mode we find $\sigma_S = 4.9 \text{ GeV} + 5.7 \times 10^{-2} M_S$ and $\sigma_V = 3.9 \text{ GeV} + 4.4 \times 10^{-2} M_V$. The global efficiencies are given in table 2 for both decay modes.

Type \ M (GeV)	50	100	150	200	
S	e eff. (%)	48	54	50	45
	ν eff. (%)	19	52	61	64
V	e eff. (%)	30	34	29	21
	ν eff. (%)	16	50	61	51
e_S	e eff. (%)	40	44	42	29

Table 2: Detection efficiency within $[M \pm 3\sigma]$ after all selection and kinematical cuts, and including trigger efficiencies for scalar (S) and vector (V) leptoquarks in $e + X$ and $\nu + X$ decay modes as well as for charged lepto gluons (e_S).

By moving a mass window of $\pm 3\sigma_{S,V}$ around the nominal central value we obtain cross section limits for scalar and vector leptoquarks. In the mass region where we observe no events (e.g. $M \gtrsim 76 \text{ GeV}$ when considering leptoquarks having couplings only to $e + X$ final states), we exclude cross sections for leptoparticle production of $\sigma_{ep \rightarrow S,V} \gtrsim 3/(\mathcal{L} \times \epsilon)$ at 95% CL, where ϵ is an efficiency derived from table 2. We exclude, e.g., $\sigma_{ep \rightarrow S^R} \gtrsim 247 \text{ pb}$ at 95% CL. From the cross section limits we derive coupling limits for all leptoquarks. Whenever possible, neutral and charged lepton decay modes have been combined. The results in the mass versus coupling constant plane are shown in fig. 2. For couplings of $\lambda = 0.3$ which corresponds to an electromagnetic coupling, i.e. $\alpha = \frac{\alpha_e^2}{4\pi}$, the mass limits at 95% CL range from 145 GeV to 192 GeV for $F = 2$ and from 98 to 121 GeV for $F = 0$ leptoquarks. The best limits are obtained for the S_0^L , $M \gtrsim 192 \text{ GeV}$ and $V_{1/2}^R$, $M \gtrsim 190 \text{ GeV}$. For the isosinglet scalars S_0^L and S_0^R which appear in particular in superstring motivated E_6 models [2], we obtain at $\lambda = 0.3$ mass limits of $M \gtrsim 181 \text{ GeV}$ and $M \gtrsim 178 \text{ GeV}$ respectively at 95% CL. We have therefore improved on the current limits from $p\bar{p}$ experiments after only a few months data taking on HERA (for the S_0^L (S_0^R) which has $B = 50\%$ (100%) into $e + X$, the CDF limit at 95% CL is 82 GeV (113 GeV) almost independently of the coupling λ).

The $\tilde{S}_{1/2}$, for which we find $M \gtrsim 98 \text{ GeV}$ at 95% CL for $\lambda = 0.3$, only couples to $e\bar{d}$ and has been proposed in a recent [22] extension of minimal $SU(5)$. The coupling limits for $\tilde{S}_{1/2}$ may also be interpreted in R-parity violating supersymmetry [23] as limits on the coupling of scalar top squark (stop) provided that a mass eigenstate of the stop exists which is lighter than the top quark and that the total decay width is dominated by R-parity violating decays.

There is an uncertainty on the limits in fig. 2 due to ambiguities in the structure function used in the calculation of leptoquark cross sections. The results presented here have been obtained using the MT-B1 parametrisation and were compared with those obtained using MT-B2, MRS-D0 and D- [24]. The differences for the limits on the

coupling constants amount to 7% for leptoquarks coupling to quarks and to 12% for those interacting with anti-quarks. For the QCD scale at which quark densities are evaluated we chose Q^2 . Alternative choices like P_T^2 and M^2 yield an additional uncertainty of 7%

Figure 2: Rejection limits at the 95% CL for the coupling $\lambda_{L,R}$ as a function of mass M (GeV) scalar and vector leptoquarks with fermion number $F=2$ (a), (b) and $F=0$ (c), (d). Regions above the curves are excluded. The limits on λ_L for S_0, S_1, V_0 and V_1 come charged and neutral decays.

4 Leptogluons

Leptogluons are colour octet states carrying lepton number which can have dimension renormalizable couplings only to gluons. At HERA, we essentially study their coupling to electron-gluon pairs for which an interaction Lagrangian, for a magnetic type couple

is given in [25]² where spin 1/2 leptogluons were considered. For such an electron-type leptogluon e_8 , chiral protection must be imposed to avoid the stringent indirect mass limits from $(g-2)_e$ measurements [26] valid for any reasonable scale Λ . We perform the analysis for couplings with left-handed electrons. For the dominant s-channel contribution, the final state angular distribution is independent of this assumption. At HERA, leptogluons would be produced as narrow s-channel resonances through the direct fusion of a lepton and a gluon from the proton. To lowest order, the cross section depends only on the gluon density $g(x, Q^2)$ in the proton at $x = M^2/s$ and on $(M/\Lambda)^2$, where M is the leptogluon mass and Λ is a scale parameter. The decay width is given by $\Gamma = \alpha_s M^3/4\Lambda^2$, where α_s is the strong coupling constant.

Limits on e_8 leptogluons were derived by JADE [14, 25] from the t-channel contribution to the total hadronic cross section, $M_{e_8} \gtrsim (240 \text{ GeV})^3/\Lambda^2$ and from direct production via one photon exchange, $M_{e_8} \gtrsim 20 \text{ GeV}$. A mass limit of $M > \mathcal{O}(110 \text{ GeV})$ from direct pair production via colour gauge interactions has also been derived from $p\bar{p}$ collider data [27].

The final state of a lepton and a gluon jet (instead of a quark jet) only differs from the one expected for leptoquarks in the details of the jet fragmentation. The analysis presented in the previous section is insensitive to the detailed topology of the hadronic final state. Hence, we make use of the event selection presented there for $e+X$ final states and the corresponding mass distribution presented in fig. 1. We also use COMPPOS [11] event generator for this analysis together with the full H1 simulation to estimate leptogluon detection efficiencies after the final $e+X$ kinematical cuts. For leptogluons, the mass resolution σ_{e_8} scales like $\sigma_{e_8} = 0.6 \text{ GeV} + 1.7 \times 10^{-2} M_{e_8}$. These efficiencies are given in table 2 as a function of mass.

Assuming that all the observed events are standard DIS background, we obtain rejection limits at the 95% CL following the procedure described in the previous section. The limits in the Λ^{-1} versus M_{e_8} plane are shown in fig. 3. We exclude at 95% CL scale parameters $\Lambda \lesssim 1.8 \text{ TeV}$ for a leptogluon at $M \simeq 100 \text{ GeV}$ and $\Lambda \lesssim 200 \text{ GeV}$ at $M \simeq 200 \text{ GeV}$.

5 Excited Leptons

5.1 Phenomenology

Strong evidence for a structure of the known fermions would be provided by the direct observation of their excited states. If they exist, such first generation lepton excited states could be produced at HERA in a collision between the incoming electron and a gauge boson radiated from the proton (quark). Excited electrons (e^*) would be generated dominantly via the exchange of low Q^2 photons whereas excited neutrinos (ν^*) would be formed at much higher Q^2 through the interchange of a W gauge boson.

The current maximum available centre of mass energy for the direct production of excited leptons at HERA is 296 GeV. This allows a mass range to be explored for the first time where the decay of the e^* and the ν^* into heavy gauge bosons (W, Z) and a light fermion may become dominant. To date, searches for e^* and ν^* have been pursued using

²This Lagrangian has been multiplied by 1/2 to be conform with the more common definition.

Figure 3: Rejection limits at the 95% CL for the inverse of the scale parameter Λ versus M for e_8 leptogluons. Values above the curve are excluded.

the decay channel with a photon in the final state. The best current rejection limit the direct single production of excited leptons were obtained by LEP experiments [28–30, 31] and exclude masses $M_{e^*} \lesssim 90 \text{ GeV}$ almost independently of the composite scale for $\Lambda \lesssim 2.5 \text{ TeV}$.

Although there is no predictive model for composite dynamics, the existence of excited states can still be tested. We make use of an effective $SU(2) \otimes U(1)$ invariant Lagrangian [32] for spin 1/2 excited states. In this model the transition magnetic couplings of an ordinary lepton (l) and an excited lepton (l^*) to a vector boson (V) the four momentum q are studied: $-i\frac{e}{\Lambda}\sigma_{\mu\nu} q^\nu (1 - \gamma_5)c_{\nu l^* l}$. Here, e is the electric charge and all the coupling constants $c_{\nu l^* l}$ are explicitly given by

$$\begin{aligned} c_{\nu l^* e} &= -(f + f')/4 \\ c_{\nu l^* \nu} &= (f - f')/4 \\ c_{Z l^* e} &= -(f \cot \theta_W - f' \tan \theta_W)/4 \\ c_{Z l^* \nu} &= (f \cot \theta_W + f' \tan \theta_W)/4 \\ c_{W e^* \nu} &= f/(2\sqrt{2} \sin \theta_W) \end{aligned}$$

where θ_W is the weak mixing angle and f and f' are free parameters associated with gauge groups $SU(2)$ and $U(1)$. The production of the excited leptons depends mainly on the couplings $c_{\nu^* e^* e}$ and $c_{W e^* \nu}$ while for the decay of the excited states the other couplings have to be considered, too. The width Γ introduced in section 1 is given by $\Gamma = \alpha M^3 c_{\nu^* l}^2 / \Lambda^2$.

The branching ratios, given in [33, 34] are a priori unknown since they depend crucially on the ratio of the free coupling parameters f and f' . If one sets $f = f' = 1$, the excited masses decays dominantly into a photon and an electron while at higher masses contribution of the charged weak boson is most significant (see table 3). However, for

choice of the parameters the ν^* can only decay into a W^+ or a Z^0 . For $f = -f' = 1$, the e^* has the photon channel completely suppressed while in this channel the ν^* has its maximal branching ratio. This complementary behaviour together with the arbitrariness of f and f' motivates a search for both the e^* and the ν^* and suggests that as many decay channels as possible should be studied.

M (GeV)	$e^* \rightarrow e\gamma$	$e^* \rightarrow eZ$	$e^* \rightarrow \nu W$	$\nu^* \rightarrow \nu\gamma$	$\nu^* \rightarrow \nu Z$	$\nu^* \rightarrow eW$
100	73 / 0	1 / 14	26 / 86	0 / 73	14 / 1	86 / 26
150	40 / 0	8 / 34	52 / 66	0 / 40	34 / 8	66 / 52
200	34 / 0	10 / 37	56 / 63	0 / 34	37 / 10	63 / 56

Table 3: Branching ratios (in %) of the three decay channels for the excited electron and neutrino. The first number in the columns refers to a setting of $f=f'=1$, the second to $f=-f'=1$.

Therefore, as well as $e^* \rightarrow e^- + \gamma$, the weak boson decay channels also have to be considered for both e^* and ν^* , leading to signatures with electrons, photons or muons in the final state. Table 4 summarizes the decay channels which are studied with the H1 detector. The production and decay of heavy excited leptons considered here, is characterized by one or more energetic e.m. clusters with high E_T in the final state. In addition in some channels a signature with one or two muons and/or missing visible energy should occur.

5.2 Event Selection

The candidate sample for excited leptons was selected by requiring isolated e.m. clusters in the H1 calorimeter. We searched for event topologies with one, two or three such clusters in the final states, and for two muon candidates together with one cluster.

Candidates for events with one-electron or one-photon must have at least one isolated e.m. cluster with more than 15 GeV. The quantity $E_T + P_T^{\text{miss}}$ was required to be greater than 30 GeV and P_T^{miss} should be above 16 GeV. Events with a single cluster in the backward region are excluded to eliminate the DIS $e\nu$ scattering at low Q^2 . For background suppression, we demand one track in the central drift chambers (with $P_T > 0.2$ GeV) or forward tracking system. The reconstruction efficiency for these tracks is determined from isolated tracks in a DIS data sample with the scattered electron in the LAr calorimeter and from muons crossing the forward chambers. The efficiencies agree with those found in Monte Carlo calculations.

To select candidates for the decay channels with two electrons or with one electron and one photon, two isolated e.m. clusters are demanded with energies above 30 GeV and 15 GeV. At least one cluster has to be in the barrel region ($15^\circ \leq \theta \leq 150^\circ$). No events are expected with both clusters in the forward and backward part of the detector from excited lepton decays.

Candidates for $e^* \rightarrow eee$ are selected requiring three isolated clusters each having an energy above 10 GeV. Here again one cluster should be in the barrel region and only one cluster may be below 10° .

The search for muon event candidates requires two reconstructed muon tracks in the muon system linked to tracks of the forward or central tracking system. Events with two muon candidates where both tracks are in the forward part of the detector have a radius of 100 cm from the beam pipe are discarded. This cut rejects mainly halo muons with induced background in the forward direction. In addition an isolated cluster with less than 5 GeV above a θ angle of 10° is required and events with a cluster in the back region are rejected. The track link efficiency as determined from cosmic muons is 95% which is in agreement with Monte Carlo expectations.

Applying the above cuts, which were motivated by Monte Carlo studies and allow a high detection efficiency for the expected signal, we finally obtain a data sample no candidate, after rejecting contamination from cosmic and halo muons with showed their tracks by a visual scan. Events in the ‘two-cluster’ class would be candidates for $e^* \rightarrow e\gamma$ decays or for the Compton process $ep \rightarrow e\gamma p(X)$ which is the natural background source for that decay channel. For a total luminosity of 24 nb^{-1} less than 0.1 event is expected from the Compton process for invariant masses of the $e\gamma$ system above 75 GeV calculated using formulae of [35]. Further studies are restricted to masses above 75 GeV since a signal at smaller masses is already ruled out by existing data.

We then determine the detector acceptance for excited leptons as a function of mass. This requires knowledge of the geometrical acceptance, the trigger efficiency for the event selection efficiency. For detailed studies, the event generator COMPOS [32] is used. This generator is based on the cross section calculated in [32] and makes use of the same structure function as for the leptoquark analysis.

The transverse and total energy LAr trigger efficiency for the cluster analysis is determined from data triggered by cosmic and halo muons. The efficiency for triggering decay channel $e^* \rightarrow e\mu\mu$ is fixed by Monte Carlo studies where the muon trigger is completely simulated. The total efficiency for an event to trigger and to survive the selection steps is then derived from the Monte Carlo simulation which includes the trigger selection steps. In table 4, values for total efficiencies are summarized for various decay channels and masses. Typical values for the total detection efficiencies are about 80%.

M (GeV)	75	100	150	200	250
$e^* \rightarrow e\gamma$	71	82	87	88	87
$e^* \rightarrow \nu W / W \rightarrow e\nu$	—	66	67	72	75
$e^* \rightarrow eZ / Z \rightarrow ee$	—	72	89	90	85
$e^* \rightarrow eZ / Z \rightarrow \mu\mu$	—	47	68	85	88
$e^* \rightarrow eZ / Z \rightarrow \nu\nu$	—	—	68	84	87
$\nu^* \rightarrow \nu\gamma$	65	73	79	83	85
$\nu^* \rightarrow eW / W \rightarrow e\nu$	—	63	75	81	83
$\nu^* \rightarrow eW / W \rightarrow \mu\nu$	—	25	62	76	84
$\nu^* \rightarrow \nu Z / Z \rightarrow ee$	—	75	81	87	91

Table 4: Total efficiencies (in %) for different decay channels and masses of the excited leptons e^* and ν^* .

In summary, after applying selection criteria which are motivated by Monte Carlo studies, no candidates are left in any of the channels under study.

5.3 Results

With a typical efficiency of 80%, cross sections above 160 pb are ruled out with 95% CL for each channel under study. This result depends only weakly on the used model.

We have calculated coupling limits as a function of the parameter c_{ν^*} , the scale parameter Λ and the square root of the branching ratios of the excited leptons introduced in section 5.1. These limits are shown in fig. 4 for different decay channels (see table 4) as a function of the mass of the excited lepton.

In principle, coupling limits can be calculated up to the maximum of the centre of mass energy of the collisions for the direct search of excited leptons. But the calculations are limited in this analysis to masses and coupling values where the decay width is below 30 GeV. This ensures that the width is always much less than the corresponding mass. For $f = 0, f' = 1$ this width is reached at $M = 215$ GeV for the excited electron and at 165 GeV for the excited neutrino. If it should happen in nature that $f = f' = 1$ then the width of 30 GeV would be obtained at 175 GeV for the e^* , whereas if $f = 1, f' = -1$ should be true, then limits for the ν^* can only be derived up to 125 GeV.

The dominant uncertainty on these limits is due to the possible choice of the different proton structure functions. Using the same functions as in section 3.3 we obtain uncertainties on the limits up to 10%.

At 100 GeV the value for $c_{e^*} \sqrt{\Lambda}$ is 7×10^{-3} GeV $^{-1}$. Values at LEP experiment at a centre of mass energy of 90 GeV for $c_{e^*} \sqrt{\Lambda}$ are about 2×10^{-4} GeV $^{-1}$ for channel $e^* \rightarrow e\gamma$. In order to reach this magnitude for a mass of 100 GeV at a mass an integrated luminosity of $O(50 \text{ pb}^{-1})$ has to be collected. In the scattering process $e^+ e^- \rightarrow \gamma\gamma$ indirect limits for $c_{e^*} \sqrt{\Lambda}$ exist [28, 29, 30], and are in the order 10^{-2} GeV $^{-1}$ up to masses of 127 GeV.

6 Conclusions

We have searched with the H1 detector for direct production of scalar and vector leptoquarks, leptogluons, excited electrons (e^*) and excited neutrinos (ν^*) in a mass extending up to ~ 250 GeV. This mass range is not accessible directly at other existing colliders.

Scalar and vector leptoquarks of all possible $SU(2) \otimes U(1)$ multiplet assignments were searched for. No evidence was found for the production of such states and coupling were calculated as a function of mass. For a coupling value of $\lambda = 0.3$ we obtain limits at 95% CL ranging from $M \gtrsim 145$ GeV to $M \gtrsim 192$ GeV for leptoquarks resulting from the fusion of an electron and a quark and from 98 to 121 GeV for leptoquarks with an antiquark. We obtain, e.g., $M > 192$ GeV for S_L^L and $M > 190$ GeV for V at 95% CL. Finally we found no evidence for leptogluons and at 95% CL exclude the region $\Lambda \lesssim 1.8$ TeV for $M \gtrsim 100$ GeV.

The analysis of the e^* and ν^* included an investigation of several decay topologies. This search for channels with electroweak bosons in the final state is possible owing to the available centre of mass energy and is necessary because depending on the mass some channels are suppressed while others are enhanced. No evidence was found for the production of e^* or ν^* . Cross sections above 160 pb are ruled out with 95% CL detection efficiency of 80%. For this direct search, limits on couplings have been presented in a new accessible mass domain.

7 Acknowledgements

We are very grateful to the HERA machine group whose outstanding efforts made the experiment possible. We wish to acknowledge the support of the DESY technical staff. We appreciate the many contributions of our engineers and technicians who constructed and maintained the detector. We thank the funding agencies for financial support of the experiment. The non-DESY members of the collaboration also wish to thank the Directorate for the hospitality extended to them.
